**Abstract.** Mobile Ambients has been proposed by Cardelli and Gordon as a foundational calculus for mobile computing. Since its introduction, the computational strength as well as the decidability of properties have been investigated for several fragments and variants of the standard calculus. We tackle the problem of reachability and we characterize a public (i.e., restriction free) fragment for which it is decidable. This fragment is obtained by removing the `open` capability and restricting the use of replication to guarded processes. Quite surprisingly, this fragment has been shown to be Turing complete by Maffei and Phillips.

## 1 Introduction

Mobile Ambients (MA) [5] is a well known formalism exploited to describe distributed and mobile systems in terms of *ambients*. An ambient is a named collection of active processes and nested sub-ambients. In the pure (i.e., without communication) version of MA only three mobility primitives are used to permit ambient and process interaction: `in` and `out` for ambient movement, and `open` to dissolve ambient boundaries.

Following the tradition of process calculi, Mobile Ambients and its dialects have been equipped with a rich variety of formal tools useful for reasoning about and verifying properties of systems specified with these calculi (see, e.g., [9, 4, 6]). Another line of research regards the analysis of the expressiveness of these calculi in order to investigate the boundary between redundant and necessary features as well as the decidability of properties. For example, the Turing completeness of several variants and fragments of Mobile Ambients is investigated in [8], while the decidability of process termination (i.e. the existence of a finite computation) is investigated for fragments of the pure version of Mobile Ambients in [2].

Besides termination, an even more interesting property is process *reachability*: the reachability problem consists of verifying whether a target process can be reached from a source process. As an example of the relevance of reachability analysis, consider the system

$$intruder[P] \mid firewall[Q]$$

where an *intruder* running the program  $P$  attacks a *firewall* executing the program  $Q$ . It is relevant to check whether the system

$$firewall[ intruder[P'] \mid Q']$$

can be reached, where the intruder has succeeded.

The unique work, to the best of our knowledge, devoted to the investigation of reachability in Mobile Ambients is by Boneva and Talbot [1]. They prove that reachability is undecidable even in a minimal fragment of pure Mobile Ambients in which both the restriction operator (used to limit the scope of ambient names) and the `open` capability are removed.

Let us consider the above example of the *intruder* and the *firewall*. Traditional reachability consists of checking whether the target process is reachable for some instantiated processes  $P'$  and  $Q'$ . In general, one may be interested in concentrating only on the structure of the target process (i.e. the intruder is inside the firewall) abstracting away from the specific programs that run inside the ambients (i.e. abstracting away from  $P'$  and  $Q'$ ). Exploiting classical reachability one should universally quantify on every possible processes  $P'$  and  $Q'$ .

To solve this problem we introduce *spatial reachability* permitting to specify a class of target processes. This class is characterized by a common structure of ambient nesting and a minimal number of processes that should be hosted inside those ambients. As an example of the use of spatial reachability consider the system

$$trojan[virus|P]|notebook[Q]$$

in which a *trojan* containing a *virus* program, and running program  $P$ , attacks a notebook running the program  $Q$ . One may be interested in checking whether the process

$$notebook[ trojan[virus|P'] | Q']$$

can be reached for any possible  $P'$  and  $Q'$  not containing ambients. Observe that *virus* is a program for which it is necessary to check the actual presence inside the ambient *trojan* in the target process (a *trojan* that does not contain a *virus* is not dangerous).

We investigate the decidability of (spatial) reachability for fragments of the public, i.e. restriction free, version of the ambient calculus. We focus our analysis on calculi without restriction in order to concentrate on ambient nesting as the unique way for structuring processes. The relevance of restriction, as a mechanism for organizing processes inside name scopes, has been deeply investigated in the context of other process calculi such as the  $\pi$ -calculus [10].

The fragment that we characterize does not contain the `open` capability and limits the use of replication to guarded processes only (e.g.,  $!n[]$  is not a valid process for this fragment). This decidability result is proved by reducing reachability of processes to reachability in Petri nets (and spatial reachability to coverability). We prove the minimality of this fragment by showing that reachability becomes undecidable when relaxing at least one of the two restrictions imposed on the fragment. The undecidability for the `open`-free fragment has been proved by Boneva and Talbot [1]. For the fragment with guarded replication, we show how to reduce the halting problem for Random Access Machines [15] (a well known Turing powerful formalism) to the (spatial) reachability problem.

## 2 Pure Public Mobile Ambients

Pure public mobile ambients, that we denote with pMA, corresponds to the restriction-free fragment of the version of Mobile Ambients without communication defined by Cardelli and Gordon in [5].

**Definition 1.** – **pMA** – *Let Name, ranged over by  $n, m, \dots$ , be a denumerable set of ambient names. The terms of pMA are defined by the following grammar:*

$$\begin{aligned} P &::= \mathbf{0} \mid M.P \mid n[P] \mid P|P \mid !P \\ M &::= \mathbf{in} \, n \mid \mathbf{out} \, n \mid \mathbf{open} \, n \end{aligned}$$

We use  $\prod_k P$  to denote the parallel composition of  $k$  instances of the process  $P$ , while  $\prod_{i \in 1..k} P_i$  denotes the parallel composition of the indexed processes  $P_i$ .

The term  $\mathbf{0}$  represents the inactive process (and it is usually omitted).  $M.P$  is a process guarded by one of the three mobility primitives (already discussed in the Introduction): after the execution of the primitive the process behaves like  $P$ . The processes  $M.P$  are referred to as *guarded processes* in the following. The term  $n[P]$  denotes an ambient named  $n$  containing process  $P$ . A process may be also the parallel composition  $P|P$  of two subprocesses. Finally, the replication operator  $!P$  is used to put in parallel an unbounded number of instances of the process  $P$ .

The operational semantics is defined in terms of a structural congruence plus a reduction relation.

**Definition 2.** – **Structural congruence** – *The structural congruence  $\equiv$  is the smallest congruence relation satisfying:*

$$\begin{aligned} P \mid \mathbf{0} &\equiv P & P \mid Q &\equiv Q \mid P \\ P \mid (Q \mid R) &\equiv (P \mid Q) \mid R & !P &\equiv P \mid !P \end{aligned}$$

**Definition 3.** – **Reduction relation** – *The reduction relation is the smallest relation  $\rightarrow$  satisfying the following axioms and rules:*

- (1)  $n[\mathbf{in} \, m.P \mid Q] \mid m[R] \rightarrow m[n[P \mid Q] \mid R]$
- (2)  $m[n[\mathbf{out} \, m.P \mid Q] \mid R] \rightarrow n[P \mid Q] \mid m[R]$
- (3)  $\mathbf{open} \, n.P \mid n[Q] \rightarrow P \mid Q$
- (4) 
$$\frac{P \rightarrow Q}{P \mid R \rightarrow Q \mid R}$$
- (5) 
$$\frac{P \rightarrow Q}{n[P] \rightarrow n[Q]}$$
- (6) 
$$\frac{P' \equiv P \quad P \rightarrow Q \quad Q' \equiv Q}{P' \rightarrow Q'}$$

As usual, we use  $\rightarrow^*$  to denote the reflexive and transitive closure of  $\rightarrow$ . If  $P \rightarrow^* Q$  we say that  $Q$  is a derivative of  $P$ . The reachability problem consists in checking, given two processes  $P$  and  $Q$ , whether  $Q$  is a derivative of  $P$ , i.e. checking if  $P \rightarrow^* Q$ .

Axioms (1), (2) and (3) describe the semantics of the three primitives **in**, **out** and **open**, respectively. A process inside an ambient  $n$  can perform an **in**  $m$  operation in presence of a sibling ambient  $m$ ; if the operation is executed then the ambient  $n$  moves inside  $m$ . If inside an ambient  $m$  there is an ambient  $n$  with a process performing an **out**  $m$  action, this results in moving the ambient  $n$  outside the ambient  $m$ . Finally, a process performing an **open**  $n$  operation has the ability to remove the boundary of an ambient  $n[Q]$  composed in parallel with it.

Rules (4) and (5) are the contextual rules that respectively indicate that a process can move also when it is in parallel with another process and when it is inside an ambient. Finally, rule (6) is used to ensure that two structurally congruent terms have the same reductions.

In the paper we consider three fragments of  $\text{pMA}$ ;  $\text{pMA}_{g!}$  and  $\text{pMA}^{-\text{open}}$  for which we show that reachability is undecidable and  $\text{pMA}_{g!}^{-\text{open}}$  for which it turns out to be decidable.

**Definition 4.**

$\text{pMA}_{g!}$  permits only guarded replication, i.e. it restricts the application of the replication operator to guarded processes:<sup>1</sup>

$$\begin{aligned} P & ::= \mathbf{0} \mid M.P \mid n[P] \mid P|P \mid !M.P \\ M & ::= \mathbf{in} \ n \mid \mathbf{out} \ n \mid \mathbf{open} \ n \end{aligned}$$

$\text{pMA}^{-\text{open}}$  removes the **open** capability:

$$\begin{aligned} P & ::= \mathbf{0} \mid M.P \mid n[P] \mid P|P \mid !P \\ M & ::= \mathbf{in} \ n \mid \mathbf{out} \ n \end{aligned}$$

$\text{pMA}_{g!}^{-\text{open}}$  combines the restrictions imposed by the previous fragments:

$$\begin{aligned} P & ::= \mathbf{0} \mid M.P \mid n[P] \mid P|P \mid !M.P \\ M & ::= \mathbf{in} \ n \mid \mathbf{out} \ n \end{aligned}$$

### 3 Deciding Reachability in $\text{pMA}_{g!}^{-\text{open}}$

In this Section we show that reachability is decidable in  $\text{pMA}_{g!}^{-\text{open}}$ . We reduce reachability on  $\text{pMA}_{g!}^{-\text{open}}$  to reachability on Place/Transition Petri nets.

---

<sup>1</sup> The structural congruence for  $\text{pMA}_{g!}$  is obtained by replacing the axiom for replication with  $!M.P \equiv M.P \mid !M.P$ , and the the congruence rule for the replication operator with the congruence rule for the operator of restricted replication.

As reachability is decidable on such class of Petri nets [13], we get the decidability result for reachability on  $\text{pMA}_{g!}^{-\text{open}}$ .

Another interesting property is spatial reachability. Given two processes,  $P$  and  $R$ , the spatial reachability problem roughly consists in checking if, starting from  $P$ , it is possible to reach a process  $R'$  “greater” than  $R$ , in the following sense: the ambients in  $R$  and  $R'$  have the same structure of ambient nesting, and the (sequential and replicated) active subprocesses inside an  $R$  ambient are a subset of the subprocesses inside the corresponding ambient in  $R'$ . The Petri net constructed for the solution of the reachability problem can be exploited to reduce the spatial reachability problem for  $\text{pMA}_{g!}^{-\text{open}}$  processes to the coverability problem for Petri nets, which is a decidable problem [14].

We start recalling Place/Transition nets with unweighed flow arcs (see, e.g., [14]).

**Definition 5.** *Given a set  $S$ , a finite multiset over  $S$  is a function  $m : S \rightarrow \mathbb{N}$  such that the set  $\text{dom}(m) = \{s \in S \mid m(s) \neq 0\}$  is finite. The set of all finite multisets over  $S$ , denoted by  $\mathcal{M}_{\text{fin}}(S)$ , is ranged over by  $m$ . We write  $m \subseteq m'$  if  $m(s) \leq m'(s)$  for all  $s \in S$ . With  $\oplus$  and  $\setminus$  we denote multiset union and multiset difference, respectively.*

**Definition 6.** *A P/T net is a pair  $(S, T)$  where  $S$  is the set of places and  $T \subseteq \mathcal{M}_{\text{fin}}(S) \times \mathcal{M}_{\text{fin}}(S)$  is the set of transitions.*

*Finite multisets over the set  $S$  of places are called markings. Given a marking  $m$  and a place  $s$ , we say that the place  $s$  contains  $m(s)$  tokens.*

*A P/T net is finite if both  $S$  and  $T$  are finite.*

*A P/T system is a triple  $N = (S, T, m_0)$  where  $(S, T)$  is a P/T net and  $m_0$  is the initial marking.*

*A transition  $t = (c, p)$  is usually written in the form  $c \rightarrow p$ . A transition  $t = (c, p)$  is enabled at  $m$  if  $c \subseteq m$ . The execution of a transition  $t$  enabled at  $m$  produces the marking  $m' = (m \setminus c) \oplus p$ . This is written as  $m \xrightarrow{t} m'$  or simply  $m \rightarrow m'$  when the transition  $t$  is not relevant.*

*We say that  $m'$  is reachable from  $m$  if there exists  $\sigma$  such that  $m \xrightarrow{\sigma} m'$ .*

*We say that  $m'$  covers  $m$  if  $m \subseteq m'$ .*

**Definition 7.** *Let  $N = (S, T, m_0)$  be a P/T system.*

*The reachability problem for marking  $m$  consists of checking if  $m_0 \rightarrow^* m$ .*

*The coverability problem for marking  $m$  consists of checking if there exists  $m'$  such that  $m_0 \rightarrow^* m'$  and  $m'$  covers  $m$ .*

### 3.1 Reducing reachability on processes to reachability on Petri nets

Now we show that reachability on processes can be reduced to reachability on Petri nets; by decidability of reachability on Petri nets, we get the following:

**Theorem 1.** *Let  $P, R$  be  $\text{pMA}_{g!}^{-\text{open}}$  processes. The reachability problem  $P \rightarrow^* R$  is decidable.*

Given two processes  $P$  and  $R$ , we outline construction of a (finite) Petri system  $Sys_{P,R}$  satisfying the following property: the check of  $P \rightarrow^* R$  is equivalent to check reachability of a finite set of markings on  $Sys_{P,R}$ . Because of the lack of space, the technical details concerning the construction of the net, as well as the auxiliary results needed to prove Theorem 1 are omitted; they can be found in [3].

The intuition behind this result relies on a monotonicity property of  $\text{pMA}_{g!}^{-\text{open}}$ : because of the absence of the **open** capability, the number of “active” ambients in a process (i.e., ambients that are not guarded by any capability) cannot decrease during the computation. Moreover, as the applicability of replication is restricted to guarded processes, the number of “active” ambients in a set of structurally equivalent processes is finite (while this is not the case in  $\nu$ , e.g., the  $\text{pMA}$  process  $!n[0]$ ). Thanks to the property explained above, in order to check if  $R$  is reachable from  $P$  it is sufficient to take into account a subset of the derivatives of  $P$ : namely, the  $P$ -derivatives whose number of active ambients is not greater than the number of active ambients in  $R$ .

Unfortunately, this subset of  $P$ -derivatives is, in general, not finite, as the processes inside an ambient can grow unlimitedly. Consider, e.g., the process  $P = m[! \text{in } n. \text{out } n.Q] \mid n[]$ : it is easy to see that, for any  $k$ ,  $m[\prod_k Q \mid ! \text{in } n. \text{out } n.Q] \mid n[]$  is a derivative of  $P$ .

On the other hand, we note that the set of *sequential* and *replicated* terms that can occur as subprocesses of (the derivatives of) a process  $P$  (namely, the subterms of kind  $M.P$  or  $!M.P$ ) is finite. The idea is to borrow a technique used to map (the public fragment of) a process algebra on Petri nets. A process  $P$  is decomposed in the (finite) multiset of its sequential subprocesses that appear at top-level (i.e., occur unguarded in  $P$ ); this multiset is then considered as the marking of a Place/Transition Petri net. The execution of a computational step in a process will correspond to the firing (execution) of a transition in the corresponding net. Thus, we reduce the reachability problem for  $\text{pMA}_{g!}^{-\text{open}}$  processes to reachability of a finite set of markings in a Place/Transition Petri net, which is a decidable problem. However, differently from what happens in process algebras, where processes can be faithfully represented by a multiset of subprocesses,  $\text{pMA}_{g!}^{-\text{open}}$  processes have a tree-like structure that hardly fits in a flat model such as a multiset.

The solution is to consider  $\text{pMA}_{g!}^{-\text{open}}$  processes as composed of two kinds of components; the tree-like structure of ambients and the family of multisets of sequential subterms contained in each ambient. As an example, consider the process

$$\text{in } n.P \mid m[\text{in } n.P \mid \text{out } n.Q \mid n[\mathbf{0}] \mid k[\mathbf{0}] \mid \text{in } n.P] \mid n[\text{in } n.P]$$

having the tree-like structure  $m[n[] \mid k[]] \mid n[]$ . Moreover, there is a multiset corresponding to each “node” of the tree: the multiset  $\{\text{in } n.P\}$  is associated to the root, the same multiset is associated to the  $n$ -labelled son of the root, the multiset  $\{\text{in } n.P, \text{in } n.P, \text{out } n.Q\}$  is associated to the  $n$ -labelled son of the  $m$ -labelled son of the root, and so on.

with  $l_2$  and  $l_3$ , and omit the two subnets labelled with  $l_0$  (with empty marking) and with  $l_1$  (whose marking consists of a token in place  $l_1 : \text{out } m$ ). The computation step  $n[\text{out } m] \mid m[\text{in } n.k[\text{out } k]] \rightarrow n[\text{out } m \mid m[k[\text{out } k]]]$  corresponds to the firing of transition  $t$  in the net.

A last remark is concerned with structural congruence: because of the structural congruence rule (6), the reachability of a process  $R$  actually correspond to decide if it is possible to reach a process that is structurally congruent to  $R$ . As we are reducing the reachability in  $\text{pMA}_g^{-\text{open}}$  to marking reachability in Petri nets, it is necessary that the set of markings, corresponding to the set of processes structurally congruent to  $R$ , is finite. We concentrate on the markings of the subnets. The top-level applications of the monoidal laws for parallel composition are automatically dealt with, as processes that are structurally congruent because of such laws are mapped on the same marking. Unfortunately, the application of the replication law permits to produce an infinite set of markings corresponding to structurally congruent processes. Take, e.g.,  $!\text{in } n.P \equiv \text{in } n.P \mid !\text{in } n.P \equiv \text{in } n.P \mid \text{in } n.P \mid \text{in } n.P \equiv \dots$  and the corresponding set of markings  $\{!\text{in } n.P\}, \{\text{in } n.P, !\text{in } n.P\}, \{\text{in } n.P, \text{in } n.P, !\text{in } n.P\}, \dots$

To solve this problem, we make use of the following two techniques.

The top-level application of the law for replication can be easily dealt with by adding the transitions  $!\text{in } n.P \rightarrow !\text{in } n.P \mid \text{in } n.P$  and  $!\text{in } n.P \mid \text{in } n.P \rightarrow !\text{in } n.P$ , respectively permitting to spawn a new copy of a replicated process and to absorb a process that also appears in a replicated form in the marking. An instance of such transitions is depicted in the subnet  $l_2$  of Figure 1.

The last problem to be dealt with is the application of the laws in combination with the congruence law for prefix and ambient. Consider, e.g., the reachability of process  $R = m[!\text{in } n.!\text{in } m.0]$ ; concerning the subnet corresponding to the  $m$ -labelled son of the root, we must check reachability of an infinite set of markings, namely,

$$\{!\text{in } n.!\text{in } m.0\}, \{!\text{in } n.(\text{in } m.0 \mid !\text{in } m.0)\}, \{!\text{in } n.(\text{in } m.0 \mid \text{in } m.0 \mid !\text{in } m.0)\}, \dots$$

To this aim, we introduce canonical representations of the equivalence classes of structural congruence, roughly consisting in nested multisets where the presence of a replicated version of a sequential term forbids the presence of any occurrence of the nonreplicated version of the same term. For example, the normal form of process  $\text{in } n.(!\text{out } m.0) \mid !\text{in } n.(\text{out } m.0 \mid !\text{out } m.0) \mid n[\text{in } n.0]$  is the nested multiset  $!\text{in } n.(!\text{out } m.0) \mid n[\text{in } n.0]$ .

Now we are ready to describe the net that will be used to decide reachability of a process  $R$  starting from a process  $P$ .

The set of places of the net is constructed as follows. The part of the net representing the tree-like structure contains a place for each tree of size not greater than the number of active ambients in  $R$ . Each of the subnets contains a place for each sequential and replicated subprocess of process  $P$ , and a place named “unused”, that remains filled as long as the subnet does not correspond to any node in the tree-like structure. Moreover, we associate a distinct label to each subnet, and all the places of the subnet will be decorated with such a label.

The net has two sets of transitions: the first set permits to model the execution of the `in` and `out` capabilities, while the second set is used to cope with the structural congruence rule for replication.

We concentrate on the first set of transitions. A capability, say, e.g., `in n`, can be executed when the following conditions are fulfilled: the tree-like structure must have a specific structure and a place corresponding to a sequential subprocess `in n.Q` is marked in a subnet whose label appears in the right position in the tree-like structure. Moreover, the number of active ambients created by the execution of the capability, added to the number of currently active ambients, must not exceed the number of active ambients in the process  $R$  we want to reach. This condition is checked by requiring that there exist a sufficient number of “unused” places that are currently marked. The execution of the capability causes the following changes to the marking of the net: the place corresponding to the new tree-like structure is now filled and the marking of the subnet performing the `in n` operation is updated (by adding the tokens in the places corresponding to the active sequential and replicated subprocesses in the continuation  $Q$ ). Moreover, a number of subnets equal to the number of active ambients in the continuation  $Q$  become active: their places will be filled with the tokens corresponding to the active sequential and replicated subprocesses contained in the corresponding ambient, and the tree-like structure is updated accordingly.

Besides deciding reachability, the net system described above can be used to check the weaker property of spatial reachability.

### 3.2 Spatial reachability

The spatial reachability problem for processes  $P$  and  $R$  roughly consists in checking if, starting from  $P$ , it is possible to reach a process  $R'$  “greater than”  $R$ , in the following sense:

- $R'$  has the same spatial ambient structure of  $R$ , and
- the sequential and replicated active subprocesses contained in each ambient of  $R$  are also present in the corresponding ambient of  $R'$ .

The  $\preceq_s$  relation is a formalization of the “greater than” concept:

**Definition 8.** *Let  $P$  and  $Q$  be  $pMA_{g!}^{-\text{open}}$  processes.*

*$P \preceq_s Q$  iff*

- *either  $Q \equiv P \mid \prod_i M_i.P_i \mid \prod_j !M'_j.P'_j$ ,*
- *or  $P \equiv P_1 \mid n[P_2]$ ,  $Q \equiv Q_1 \mid n[Q_2]$  and  $P_i \preceq_s Q_i$  for  $i = 1, 2$*

The spatial reachability problem for processes  $P$  and  $R$  consists in checking if there exists  $R'$  such that  $P \rightarrow^* R'$  and  $R \preceq_s R'$ .

The mapping of processes to Petri nets markings outlined above satisfies the following property: if  $P_1 \preceq_s P_2$  then the marking corresponding to  $P_2$  covers the marking corresponding to  $P_1$ . Hence, the Petri net constructed in the previous section permits to reduce the spatial reachability problem for processes  $P$  and  $R$  to a coverability problem. As coverability is decidable in P/T nets, we obtain the following:

**Theorem 2.** *Let  $P, R$  be  $\text{pMA}_{g!}^{-\text{open}}$  processes. The spatial reachability problem for  $P$  and  $R$  is decidable.*

## 4 Undecidability Results

In this section we discuss the undecidability of reachability for the two fragments  $\text{pMA}^{-\text{open}}$  and  $\text{pMA}_{g!}$ .

As far as  $\text{pMA}^{-\text{open}}$  is concerned, we resort to an equivalent result proved by Boneva and Talbot in [1] for a slightly different calculus. That calculus, proposed in [6, 7], differs from  $\text{pMA}^{-\text{open}}$  only for three extra rules in the definition of the structural congruence relation:  $\mathbf{0} \equiv \mathbf{0}$ ,  $!P \equiv !P$ ,  $!(P \mid Q) \equiv !P \mid !Q$ . These rules are added by Boneva and Talbot to guarantee that the congruence relation is confluent, thus decidable.

The undecidability of reachability is proved by Boneva and Talbot showing how to encode two-counters machines [11], a well known Turing powerful formalism. The encoding preserves the *one-step property*: if the two-counters machine  $2CM$  moves in one step to  $2CM'$  then  $\llbracket 2CM \rrbracket \rightarrow^* \llbracket 2CM' \rrbracket$ , where  $\llbracket \cdot \rrbracket$  is the considered encoding. Even if the calculus in [1] is slightly different from  $\text{pMA}^{-\text{open}}$ , the encoding of two-counters presented in that paper applies also to our calculus; this because the encoding does not apply the replication operator to the empty process, to replicated processes and to parallel composition of processes (i.e. the cases in which the three extra structural congruence rules come into play, respectively).

As far as  $\text{pMA}_{g!}$  is concerned, we present a modeling of Random Access Machines (RAMs) [15], a formalism similar to two-counters machines. The encoding that we present is an enhancement of the RAM modeling in [2]: the main novelties are concerned with a more restricted use of replication and a reshaping of the garbage processes.

### 4.1 Random Access Machines

RAMs are a computational model based on finite programs acting on a finite set of registers. More precisely, a RAM  $R$  is composed of the registers  $r_1, \dots, r_n$ , that can hold arbitrary large natural numbers, and by a sequence of indexed instructions  $(1 : I_1), \dots, (m : I_m)$ . In [12] it is shown that the following two instructions are sufficient to model every recursive function:

- $(i : \text{Succ}(r_j))$ : adds 1 to the contents of register  $r_j$  and goes to the next instruction;
- $(i : \text{DecJump}(r_j, s))$ : if the contents of the register  $r_j$  is not zero, then decreases it by 1 and goes to the next instruction, otherwise jumps to the instruction  $s$ .

The computation starts from the first instruction and it continues by executing the other instructions in sequence, unless a jump instruction is encountered. The execution stops when an instruction number higher than the length of the

program is reached. It is not restrictive to assume that the instruction number reached at the end of the computation is always  $m + 1$ , and to assume that the computation starts and terminates with all the registers empty.

## 4.2 Modelling RAMs in $\mathbf{pMA}_g!$

We model instructions and registers independently. As far as the instructions and the program counter are concerned, we model the program counter  $i$  with an ambient  $pc_i$ . Each instruction  $I_i$  is represented with a replicated process guarded by the capability  $\mathbf{open} pc_i$  able to open the corresponding program counter ambient  $pc_i$ . The processes modeling the instructions are replicated because each instruction could be performed an unbounded amount of times during the computation.

The key idea underlying the modeling of the registers is to represent natural numbers with a corresponding nesting of ambients. We use an ambient named  $z_j$  to represent the register  $r_j$  when it is empty; when the register is incremented we move the ambient  $z_j$  inside an ambient named  $s_j$ , while on register decrement we dissolve the outer  $s_j$  ambient boundary. In this way, for instance, the register  $r_j$  with content 2 is modeled by the nesting  $s_j[s_j[z_j]]$  (plus other processes hosted in these ambients that are discussed in the following).

**Definition 9.** *Given the RAM  $R$  with instructions  $(1 : I_1), \dots, (m : I_m)$  and registers  $r_1, \dots, r_n$  we define  $\llbracket R \rrbracket$  as the following process*

$$pc_1 \mid \prod_{i \in 1 \dots m} !\mathbf{open} pc_i.C_i \mid \prod_{j \in 1 \dots n} R_j^0 \mid \mathbf{open} pc_{m+1}.GC \mid !\mathbf{open} msg \mid garbage[\mathbf{open} gc]$$

where  $C_i$  (modeling the  $i$ -th instruction),  $R_j^0$  (modeling the empty register  $r_j$ ) and  $GC$  (the garbage collector which is started at the end of the computation) are shorthand notations defined in the following.

Note the use of two extra processes:  $!\mathbf{open} msg$  used to open ambients containing messages produced during the computation and the ambient  $garbage[\mathbf{open} gc]$  which is a container for the produced garbage. The process  $\mathbf{open} gc$  is used at the end of the computation to allow the garbage collector to act inside the ambient  $garbage$  as detailed in the following.

The register  $r_j$  with content  $l$  is represented by the process  $R_j^l$  defined inductively as follows

$$\begin{aligned} R_j^0 &= z_j[ !\mathbf{open} inc_j. \\ &\quad ( msg[ \mathbf{out} z_j.s_j[ REG_j ] ] \mid \\ &\quad \mathbf{in} s_j.ack_i_j[ \mathbf{out} z_j.\mathbf{out} s_j ] ) \mid \\ &\quad !\mathbf{open} zero_j.ack_z_j[ \mathbf{out} z_j.\mathbf{in} dj_j ] \mid \\ &\quad \mathbf{open} gc ] \\ R_j^{l+1} &= s_j[ REG_j \mid R_j^l ] \end{aligned}$$

where  $REG_j$  is a shorthand notation defined as follows

$$REG_j = \mathbf{open} dec_j.ack_d_j[ \mathbf{out} s_j.\mathbf{in} dj_j ] \mid !\mathbf{open} msg$$

Also in this case, the process `open gc` is used to allow the garbage collector to act inside the ambient  $z_j$ . We will discuss the behaviour of the term  $REG_j$ , and of the other processes inside the ambient  $z_j$ , after having discussed the encoding for the instructions.

Before formalizing the modeling of the instructions we anticipate that the names  $inc_j$ ,  $zero_j$  and  $dec_j$  are used to model requests for increment, test for zero and decrement of register  $r_j$ , respectively; the names  $acki_j$ ,  $ackz_j$  and  $ackd_j$  models the corresponding acknowledgements produced by the registers to notify that a request has been managed.

The instructions are modeled as follows. If the  $i$ -th instruction is  $Succ(r_j)$ , its encoding is

$$C_i = increq_j[ !in s_j \mid in z_j.inc_j[out increq_j] ] \mid \text{open } acki_j.pc_{i+1}[]$$

This modeling is based on two processes. The first one is the ambient  $increq_j$  that represents a request for increment of the register  $r_j$ . The second process blocks waiting for an acknowledgement that will be produced after the actual increment of the register; when the acknowledgement is received, this process increments the program counter spawning  $pc_{i+1}[]$ .

The ambient  $increq_j$  has the ability to enter the boundary of the ambient modelling the register  $r_j$ , to move through the nesting of ambients, and finally to enter the inner ambient  $z_j$ . After that, a new ambient  $inc_j$  exits the ambient  $increq_j$  becoming in parallel with the processes of the ambient  $z_j$ . One of these processes (see the definition of  $R_j^0$ ) detects the arrival of the new ambient and reacts by producing  $s_j[REG_j]$ ; the ambient  $z_j$  then moves inside this new ambient. In this way the nesting of ambients  $s_j$  is incremented by one. After, the acknowledgement is produced in terms of an ambient named  $acki_j$  that moves outside the register boundary.

If the  $i$ -th instruction is  $DecJump(r_j, s)$  the encoding is as follows

$$C_i = zero_j[in z_j] \mid dec_j[in s_j] \mid dj_j[ ACKZ_{js} \mid ACKD_{ji} ]$$

where

$$\begin{aligned} ACKZ_{js} &= \text{open } ackz_j.in \text{ garbage.} \\ &\quad msg[ out dj_j.out \text{ garbage.open } dec_j.pc_s[] ] \\ ACKD_{ji} &= \text{open } ackd_j.in \text{ garbage.} \\ &\quad msg[ out dj_j.out \text{ garbage.open } zero_j.open s_j.pc_{i+1}[] ] \end{aligned}$$

This modeling is based on three processes. The first process is an ambient named  $zero_j$  which represents a request for a test for zero of the register  $r_j$ ; the second process is an ambient named  $dec_j$  representing a request for decrement of the register  $r_j$ ; the third process is an ambient named  $dj_j$  which is in charge to manage the acknowledgement produced by the register  $r_j$ . The acknowledgement indicates whether the decrement, or the test for zero request, has succeeded.

Let us consider the test for zero request. The ambient  $zero_j[\mathbf{in} z_j]$  has the ability to move inside the ambient  $z_j$ . This can occur only if the register  $r_j$  is currently empty; in fact, if  $r_j$  is not empty, the ambient  $z_j$  is not at the outer level. If the request enters the  $z_j$  ambient boundary, the processes inside the ambient  $z_j$  (see the definition of  $R_j^0$ ) react by producing an acknowledgement modelled by an ambient named  $ackz_j$  which moves inside the ambient  $dj_j$ .

Now, consider the request for decrement. The ambient  $dec_j[\mathbf{in} s_j]$  has the ability to enter the boundary of the process modelling the register  $r_j$ ; this can occur only if the register is not empty (otherwise there is no ambient  $s_j$ ). Inside the ambient  $s_j$ , the process  $REG_j$  reacts by producing an acknowledgement modelled by an ambient named  $ackd_j$  which moves inside the ambient  $dj_j$ .

The processes inside the ambient  $dj_j$  have the ability to detect which kind of acknowledgement has been produced, and react accordingly. In case of  $ackz_j$ , the reaction is to move the ambient  $dj_j$  inside the ambient *garbage*, and to dissolve the boundary of the outer ambient  $dec_j$ . This is necessary to remove the decrement request that has failed. In case of  $ackd_j$ , the process also dissolves one of the boundaries  $s_j$ , in order to actually decrement the register. In both cases, the program counter is finally updated by either jumping to instruction  $s$ , or by activating the next instruction  $i + 1$ , respectively.

This way of modeling RAMs does not guarantee the one-step preservation property because of the production of garbage, that is processes that are no more involved in the subsequent computation. More precisely, the following garbage is produced:

- each increment operation leaves an ambient  $increq_j[\mathbf{in} s_j]$  inside the ambient  $z_j$ , plus the process  $\mathbf{out} s_j$  at the outer level;
- each decrement operation leaves an ambient  $dj_j$  inside the ambient *garbage*, plus the two processes  $\mathbf{in} z_j$  and  $\mathbf{!open} msg$  at the outer level;
- each test for zero operation leaves an ambient  $dj_j$  inside the ambient *garbage*, plus the process  $\mathbf{in} s_j$  at the outer level.

Clearly, the exact shape of the garbage at the end of the modeling of the RAM computation is unpredictable because it depends on the exact number of instructions that are executed. Nevertheless, we use the garbage collector process  $GC$ , activated on program termination, in order to reshape the garbage in a predefined format.

The key idea underlying the garbage collection process is to exploit the structural congruence rule  $\mathbf{!}P \equiv P \mid \mathbf{!}P$  used to unfold (and fold) replication. Consider an unpredictable amount of processes  $P$  in parallel, i.e.  $\prod_n P$  with  $n$  unknown. If we add in parallel the process  $\mathbf{!}P$  we have that  $\prod_n P \mid \mathbf{!}P \equiv \mathbf{!}P$ , thus reshaping the process in a known format.

We are now in place for defining the garbage collector process formally

$$\begin{aligned}
GC = & \mathbf{!out} s_j \mid \mathbf{!in} z_j \mid \mathbf{!open} msg \mid \mathbf{!in} s_j \mid \\
& \prod_{j \in 1 \dots n} (gc[ \mathbf{in} z_j.(\mathbf{!open} increq_j \mid \mathbf{!in} s_j) ] ) \mid \\
& gc[ \mathbf{in} garbage \mid \\
& \quad \prod_{j \in 1 \dots n} ( \mathbf{!open} dj_j \mid \prod_{i \in 1 \dots m} \mathbf{!ACKD}_{ji} \mid \\
& \quad \quad \prod_{s \in 1 \dots m+1} \mathbf{!ACKZ}_{js} ) ]
\end{aligned}$$

The undecidability of reachability and spatial reachability is a trivial corollary of the following theorem. It is worth noting that in the statement of the theorem the register  $r_j$  (which is assumed to be empty at the end of the computation) is represented by a process which is the same as  $R_j^0$  with the difference that the process `open gc`, initially available in the ambient  $z_j$  (see the definition of  $R_j^0$ ), is replaced by the two processes `!open increq | !!in s_j` left by the garbage collector.

**Theorem 3.** *Given the RAM  $R$  with instructions  $(1 : I_1), \dots, (m : I_m)$  and registers  $r_1, \dots, r_n$  we have that  $R$  terminates if and only if*

$$\begin{aligned} & \prod_{i \in 1 \dots m} \text{!open } pc_i.C_i \mid \\ & \prod_{j \in 1 \dots n} ( z_j [ \text{!open } inc_j. \\ & \quad ( \text{msg} [ \text{out } z_j.s_j [ REG_j ] ] \mid \\ & \quad \quad \text{in } s_j.ack_{i,j} [ \text{out } z_j.\text{!out } s_j ] ) \mid \\ & \quad \text{!open } zero_j.ack_{z_j} [ \text{out } z_j.\text{in } dj_j ] \mid \\ & \quad \text{!open } increq_j \mid !!\text{in } s_j ] ) \mid \\ & \text{!out } s_j \mid \text{!in } z_j \mid \text{!open } msg \mid \text{!in } s_j \mid \\ & \text{garbage} [ \prod_{j \in 1 \dots n} ( \text{!open } dj_j \mid \prod_{i \in 1 \dots m} \text{!ACKD}_{ji} \mid \\ & \quad \prod_{s \in 1 \dots m+1} \text{!ACKZ}_{js} ) ] \end{aligned}$$

is reachable from the process  $\llbracket R \rrbracket$  (as defined in Definition 9).

Moreover, we have that the RAM  $R$  terminates if and only if the process

$$pc_{m+1} [] \mid \prod_{j \in 1 \dots n} z_j [] \mid \text{garbage} []$$

is spatially reachable from the process  $\llbracket R \rrbracket$ .

## 5 Conclusion

We have discussed the decidability of reachability in Mobile Ambients. We have characterized a fragment of the pure and public Mobile Ambients, namely the `open`-free fragment with guarded replication, for which reachability is decidable. We call this fragment  $\text{pMA}_{g!}^{-\text{open}}$ . Our decidability result also holds for a variant of reachability, called spatial reachability, that permits to specify a class of target processes characterized by a common structure of ambient nesting.

The fragment  $\text{pMA}_{g!}^{-\text{open}}$  has been already investigated by Maffei and Phillips in [8] (called  $L_{io}$  in that paper). They show that such a small fragment is indeed Turing complete, by providing an encoding of RAMs. The encoding they present permits to conclude that the existence of a terminating computation is an undecidable problem, while the decidability of reachability is raised as an open problem. Our decidability result provides a positive answer to this problem.

In order to prove the minimality of  $\text{pMA}_{g!}^{-\text{open}}$  we make use of (a slight adaptation of) the undecidability result by Boneva and Talbot [1]. They prove that reachability is undecidable for the `open`-free fragment, equipped with a structural congruence slightly different from the standard one (see the discussion in Section 4). Instead of getting decidability by imposing syntactical restrictions

(as we do for  $\text{pMA}_{g^!}^{-\text{open}}$ ), they move to a weaker version of the operational semantics. In particular, they show that reachability becomes decidable when the structural congruence law  $!P \equiv P \mid !P$  is replaced by the reduction axiom  $!P \rightarrow P \mid !P$ .

**Acknowledgements** We thank Jean-Marc Talbot and Iain Phillips for their insightful comments on a preliminary version of this paper.
